# miniKanren with fair search strategies

KUANG-CHEN LU, Indiana University

WEIXI MA, Indiana University
DANIEL P. FRIEDMAN, Indiana University

The syntax of a programming language should reflect its semantics. When writing a cond<sup>e</sup> expression in miniKanren, a programmer would expect all clauses share the same chance of being explored, as these clauses are written in parallel. The existing search strategy, interleaving DFS (iDFS), however, prioritize its clauses by the order how they are written down. Similarly, when a cond<sup>e</sup> is followed by another goal conjunctively, a programmer would expect states in parallel share the same chance of being explored. Again, the answers by iDFS is different from the expectation. We have devised three new search strategies that have different level of fairness in disjand conj.

#### **ACM Reference Format:**

## 1 INTRODUCTION

miniKanren programs, especially relational interpreters, have been proven to be useful in solving many problems [1]. A subtlety in writing relational programs having large cond<sup>e</sup> expressions, such as interpreters, is that the order of cond<sup>e</sup> clauses can affect the speed considerably. When a cond<sup>e</sup> expression is large enough, the left clauses consume almost all the resource and the right ones are hardly explored. The unfair disj of the current search strategy, interleaving DFS, is the cause. Under the hood, cond<sup>e</sup> uses conj to create a goal for each clause, and disj to combine these goals to one. The current disj allocates half resource to its first goal, then allocates the other half to the rest similarly, except for the last clause which takes all the resource.

Being aware of disj fairness, we also investigate conj fairness.

We propose three new search strategies, balanced interleaving DFS (biDFS), fair DFS (fDFS), and BFS. They have different characteristics of fairness (Table. 1). We prove that the pure subset of our BFS and the BFS proposed by Seres et al [4] produce the same result when queried. But our code is shorter and runs faster. Because the two BFSs are equivalent, we do not distinguish them in most places.

## 2 FAIRNESS

We demonstrate the aspects (disj or conj) and levels (unfair, almost-fair, or fair) of fairness by running queries about repeato, a relational definition that relates a term x with a non-empty list whose elements are x (Fig. 1).

disj	unfair	almost-fair	fair	fair
conj	unfair	unfair	unfair	fair

Table 1. fairness of search strategies

Fig. 1. repeato and an example run

# 2.1 fair disj

 In the following program, the three cond<sup>e</sup> clauses differ in a trivial way. So we expect lists of each sort constitute 1/4 of the answer list. However, iDFS, the current search strategy, gives us much more lists of a than other sorts of lists. And some sorts (e.g. lists of c) are hardly found. The situation would be worse if we add more cond<sup>e</sup> clauses.

We borrow the definition of fair disj from [4]: search strategies with fair disj should allocate resource evenly among disjunctive goals. Running the same program with fDFS and BFS give the following result.

```
;; fDFS and BFS (fair disj)
> (run 12 q
    (conde
      [(repeato 'a q)]
      [(repeato 'b q)]
      [(repeato 'c q)]
      [(repeato 'd q)]))
'((a) (b) (c) (d)
  (a a) (b b) (c c) (d d)
  (a a a) (b b b) (c c c) (d d d))
```

We conceive a middle place between fair and unfair – search strategies with almost-fair disj should allocate resource so evenly among disjunctive goals [4] that the maximal ratio of resource is bounded by a constant. Our new search strategy, biDFS, has almost-fair disj. It is fair when the number of goals is a power of 2, otherwise, some goals are allocated twice more resource than the others. In the previous example, it gives the same result. And in the following example, where the cond<sup>e</sup> has 5 clause, the clauses of b, c, and d are allocated more resource.

```
;; biDFS (almost-fair disj)
> (run 16 q
    (conde
      [(repeato 'a q)]
      [(repeato 'b q)]
      [(repeato 'c q)]
      [(repeato 'd q)]
      [(repeato 'e q)]))
'((b) (c) (d) (a)
  (b b) (c c) (d d) (e)
  (b b b) (c c c) (d d d) (a a)
  (b b b b) (c c c c) (d d d d) (e e))
```

In the following program, the three cond<sup>e</sup> clauses differ in a trivial way. So we expect lists of each sort constitute 1/4 of the answer list. However, search strategies with unfair conj (e.g. iDFS, fDFS) give us much more lists of a than other sorts of lists. And some sorts (e.g. lists of c) are hardly found. Although iDFS's disj is unfair in general, it is fair when there is no call to relational definition in sub-goals, including this case. The situation would be worse if we add more cond<sup>e</sup> clauses. The result with biDFS, whose conj is also unfair, is similar, but due to its different disj, the position of b and c are swapped.

```

177

 Intuitively, search strategies with fair conj should produce each sort of lists equally frequently. Indeed, BFS does so.

A more interesting situation is when the first conjunctive goal produces infinite many states. Consider the following example, a naive specification of fair conj might require search strategies to produce all sorts of singleton lists, but no longer ones, which makes the strategies *incomplete*.

, Vol. 1, No. 1, Article . Publication date: May 2019.

2019-05-01 21:55. Page 4 of 1-11.

Our solution is requiring a search strategy with *fair* conj to package states in bags, where each bag contains finite states, and to allocate resource evenly among search spaces derived from states in the same bag. The way to package depends on search strategy. And how to allocate resource among search space related to different bags is unspecified. Our definition of fair conj is orthogonal with completeness. For example, a naively fair strategy is fair but not complete, while BFS is fair and complete.

BFS packages states by their costs. The *cost* of a state is its depth in the search tree (i.e. the number of calls to relational definitions required to find them) [4]. In the following example, the cost of an answer is equal to the length of the inner lists plus the length of the outer list. Noted that BFS produces answers in increasing order of cost.

# 3 BALANCED INTERLEAVING DEPTH-FIRST SEARCH

Balanced interleaving DFS (biDFS) has almost-fair disj and unfair conj. The implementation of biDFS differs from iDFS in the disj macro. We list the new disj with its helpers in Fig. 2. The first helper function, split, takes a list of goals ls and a procedure k, partitions ls into two sub-lists of roughly equal length, and returns the application of k to the two sub-lists. disj\* takes a non-empty list of goals gs and returns a goal. With the help of split, it essentially constructs a balanced binary tree where leaves are elements of gs and nodes are disj2, whence the name of this search strategy. In contrast, the disj in iDFS essentially constructs the same sort of binary tree in one of the most unbalanced forms.

## 4 FAIR DEPTH-FIRST SEARCH

 $\frac{197}{198}$ 

 $\frac{234}{235}$ 

Fair DFS (fDFS) has fair disj and unfair conj. The implementation of fDFS differs from iDFS's in disj2 (Fig. 3). disj2 is changed to call a new and fair version of append-inf. append-inf/fair immediately calls its helper, append-inf/fair^, with the first argument, s?, set to #t, which indicates that s-inf and t-inf haven't been swapped. The swapping happens at the third cond clause in the helper, where s? is updated accordingly. The first two cond clauses essentially copy the cars and stop recursion when one of the input spaces is obviously finite. The third clause, as we mentioned early, is just for swapping. When the fourth and last clause runs, we know that both s-inf and t-inf are ended with a thunk. In this case, a new thunk is constructed. The new thunk calls the driver recursively. Here changing the order of t-inf and s-inf won't hurt the fairness (though it will change the order of answers). We swapped them back so that answers are produced in a more natural order.

```
236
     #| [Goal] x ([Goal] x [Goal] -> Goal) -> Goal |#
237
     (define (split ls k)
238
       (cond
239
          [(null? ls) (k '() '())]
240
         [else (split (cdr ls)
241
                   (lambda (l1 l2)
242
                     (k (cons (car ls) 12) 11)))]))
243
244
     #| [Goal] -> Goal |#
245
     (define (disj* gs)
246
247
       (cond
248
          [(null? (cdr gs)) (car gs)]
249
         [else
250
           (split gs
251
             (lambda (gs1 gs2)
252
               (disj2 (disj* gs1)
253
                       (disj* gs2))))]))
254
255
     (define-syntax disj
256
       (syntax-rules ()
257
         [(disj) fail]
258
         [(disj g ...) (disj* (list g

279 280

281 282 BFS is fair in both disj and conj. Our implementation is based on fDFS (not iDFS). All we have to do is apply two trivial changes to append-map-inf. First, rename it to append-map-inf/fair. Second, replace its use of append-inf to append-inf/fair.

The implementation can be improved in two aspects. First, as we mentioned in section 2.2, our BFS bag states by their cost. However, in this implementation, it is unclear where this information is recorded. Second, append-inf/fair is extravagant in memory usage. It makes O(n+m) new cons cells every time, where n and m are the "length"s of input search spaces. We address these issues in the first subsection.

Both our BFS and Seres's BFS [4] produce answers in increasing order of cost. So it is interesting to see if they are equivalent. We prove so in Coq. The details are in the second subsection.

#### 5.1 optimized BFS

As we mentioned in section 2.2, our BFS bag states by their cost. The bagging information is recorded subtly – the cars of a search space have cost 0 (i.e. they are in the same bag), and the costs of states in thunk are computed recursively then increased by one. It is even more subtle that append-inf/fair and the append-map-inf/fair respects the cost information. We make these facts more obvious by changing the type of search space, modifying related function definitions, and introducing a few more functions.

```
283
    #| Goal x Goal -> Goal |#
284
    (define (disj2 g1 g2)
285
       (lambda (s)
286
         (append-inf/fair (g1 s) (g2 s))))
287
288
    #| Space x Space -> Space |#
289
    (define (append-inf/fair s-inf t-inf)
290
       (append-inf/fair^ #t s-inf t-inf))
291
292
    #| Bool x Space x Space -> Space |#
293
294
    (define (append-inf/fair^ s? s-inf t-inf)
295
       (cond
296
         ((pair? s-inf)
297
          (cons (car s-inf)
298
            (append-inf/fair^ s? (cdr s-inf) t-inf)))
299
         ((null? s-inf) t-inf)
300
         (s? (append-inf/fair^ #f t-inf s-inf))
301
         (else (lambda ()
302
                  (append-inf/fair (t-inf) (s-inf)))))
303
304
```

Fig. 3. How fDFS differs from iDFS

The new type is a pair whose car is a list of state (the bag), and whose cdr is either a #f or a thunk returning a search space. A falsy cdr means the search space is obviously finite.

Functions related to the pure subset are listed in Fig. 4 (the others in Fig. 5). We take them apart because they are compared with Seres's implementation later. The first three functions in Fig. 4 are search space constructor. none makes an empty search space. unit makes an space from one state. step makes a space from a thunk. The remaining functions do the same thing as before.

Luckily, the change in append-inf/fair also fixes the miserable space extravagance – the use of append helps us to reuse the first bag of t-inf.

Noted that some functions here constitute a MonadPlus: none, unit, append-map-inf, and append-inf correspond to mzero, unit, bind, and mplus respectively.

Functions implementing impure features are in Fig. 5. The first function, elim, takes a space s-inf and two continuations ks and kf. When s-inf contains some states, ks is called with the first state and the rest space. Otherwise, kf is called with no argument. Here 's' and 'f' means 'succeed' and 'fail' respectively. This function is an eliminator of search space, whence the name. The remaining functions do the same thing as before.

## 5.2 comparison with Silvija's BFS

In this section, we compare the pure subset of our optimized BFS with the BFS found in [4]. We focus on the pure subset because Silvija's system is pure. Her system represents search spaces with streams of lists of states, where each list is a bag.

Fig. 4. interface functions in optimized BFS (pure)

To compare efficiency, we translate her Haskell code into Racket (See supplements for the translated code). The translation is fairly straightforward due to the similarity in both logic programming system and search space representation. The translated code is longer and slower. Details about efficiency difference are in section 6.

We prove the two search strategies are equivalent in Coq. Since search space can be infinite, we should use a co-inductive data type. However, Coq is too strict in the guardedness condition to accept a direct translation of the implementations. Therefore, we prove core theorems with finite search space instead. In

Fig. 5. interface functions in optimized BFS (impure)

order to generalize the conclusion to the cases with infinite search space, we prove a few more theorems saying that whenever we query answers lower than some finite cost, we can restrict goals to truncate search spaces at some finite depth without changing the query result. (See supplements for the formal proof)

In this section, we compare the efficiency of search strategies. A concise description is in Table 2. A hyphen means running out of memory. The first two benchmarks are taken from [2]. reverso is from [3]. Next two benchmarks about quine are modified from a similar test case in [1]. The modifications are made to circumvent the need for symbolic constraints (e.g.  $\neq$ , absento). Our version generates de Bruijnized expressions and prevent closures getting into list. The two benchmarks differ in the condeclause order of their relation interpreters. The last two benchmarks are about synthesizing expressions that evaluate to '(I love you). This benchmark is also inspired by [1]. Again, the sibling benchmarks differ in the condeclause order of their relation interpreters. The first one has elimination rules (i.e. application, car, and cdr) at the end, while the other has them at the beginning. We conjecture that iDFS would perform badly in the second case because elimination rules complicate the problem when running backward. The evaluation supports our conjecture.

Table 2. The results of a quantitative evaluation: running times of benchmarks in milliseconds

In general, only iDFS and biDFS constantly perform well. fDFS is just as efficient in all benchmarks but very-recursiveo. Both BFS have obvious overhead in many cases. Among the three variants of DFS (they all have unfair conj), fDFS is most resistant to clause permutation, followd by biDFS then iDFS. Among the two implementation of BFS, ours constantly performs as well or better. Interestingly, every strategies with fair disj suffers in very-recursiveo and fDFS performs well elsewhere. Therefore, this benchmark might be a special case. Fair conj imposes overhead constantly except in appendo. The reason might be that strategies with fair conj tend to keep more intermediate states in the memory.

# 7 RELATED WORKS

Edward points out a disjunct complex would be 'fair' if it is a full and balanced tree [5].

Silvija et al [4] also describe a breadth-first search strategy. We proof their BFS is equivalent to ours. However, ours looks simpler and performs better in comparison with a straightforward translation of their Haskell code.

## 8 CONCLUSION

We analysis the definitions of fair disj and fair conj, then propose a new definition of fair conj. Our definition is orthogonal with completeness.

We devise three new search strategies: balanced interleaving DFS (biDFS), fair DFS (fDFS), and BFS. biDFS has almost-fair disj and unfair conj. fDFS has fair disj and unfair conj. BFS has both fair disj and fair conj.

Our quantitative evaluation shows that biDFS and fDFS are competitive alternatives to iDFS, the current search strategy, and that BFS is less practical.

We prove our BFS is equivalent to the BFS in [4]. Our code is shorter and runs faster than a direct translation of their Haskell code.
